Abstract

Introduction

Since the introduction of single-cell RNA-seq technology, the number of studies that utilize single-cell RNA-seq has grown rapidly[1]. Unlike its predecessor, bulk RNA-seq, which averages the profiles of all cells within a sample, single-cell technology quantifies gene expression in individual cells. Tumors are known to be transcriptionally heterogeneous, so many studies have highlighted the importance of using single-cell RNA-seq in studying tumor samples [2]. Researchers can use tumor single-cell RNA-seq to analyze and identify individual cell populations that may play important roles in tumor growth, resistance, and metastasis [3]. Additionally, single-cell RNA-seq data provides insight into how tumor cells may be interacting with normal cells in the tumor microenvironment[4].

With the growing number of single-cell RNA-seq datasets, efforts have emerged to create central, harmonized sources for datasets. Harmonized data resources allow researchers to leverage more samples from various biological contexts to complete their analysis and elucidate previously unknown similarities across samples and disease types. The Human Cell Atlas (HCA) and Human Tumor Atlas Network (HTAN) are two of many such examples. The HCA, which aims to use single-cell genomics to provide a comprehensive map of all cell types in the human body [5], contains uniformly processed single-cell RNA-seq data obtained from normal tissue with few samples derived from diseased tissue. The HTAN also hosts a collection of genomic data collected from tumors across multiple cancer types, including single-cell RNA-seq [6].

Existing resources have focused on making large quantities of harmonized data from normal tissue or adult tumor samples publicly available, but there are considerably fewer efforts to harmonize and publicize data from pediatric tumors. Pediatric cancer is much less common than adult cancer, so the number of available samples from pediatric tumors is smaller compared to the number of adult tumors [7]. Additionally, not every institution has access to data from pediatric tumors. Thus, it is imperative to provide harmonized data from pediatric tumors to all pediatric cancer researchers [8]. To address this unmet need, Alex's Lemonade Stand Foundation and the Childhood Cancer Data Lab developed and maintain the Single-cell Pediatric Cancer Atlas (ScPCA) Portal (https://scpca.alexslemonade.org/), an open-source data resource for single-cell and single-nuclei RNA sequencing data of pediatric tumors.

The ScPCA Portal holds uniformly processed summarized gene expression from 10X Genomics' droplet-based single-cell and single-nuclei RNA-seq for over 500 samples from a diverse set of over 50 types of pediatric cancers. Originally comprising data from 10 projects funded by Alex's Lemonade Stand Foundation, the Portal has since expanded to include data contributed by pediatric cancer research community members. In addition to gene expression data from single-cell and single-nuclei RNA-seq, the Portal includes data obtained from bulk RNA-seq, spatial transcriptomics, and feature barcoding methods, such as ADT/CITE-seq and cell hashing. All data provided on the portal are available in formats ready for downstream analysis, such as SingleCellExperiment or AnnData, with objects containing normalized gene expression counts, dimensionality reduction results, and cell type annotations.

To ensure that all current and future data on the Portal are uniformly processed, we created scpca-nf, a Nextflow-based open-source pipeline (https://github.com/AlexsLemonade/scpca-nf). Using a consistent pipeline for all data increases transparency and allows users to perform analysis across multiple samples and projects without having to do any re-processing. The scpca-nf workflow uses alevin-fry [9] for fast and efficient quantification of gene expression for all samples on the Portal, including single-cell RNA-seq data and any associated ADT/CITE-seq or cell hash data, spatial

transcriptomics data, and bulk RNA-seq data. The scpca-nf pipeline also serves as a resource for the community, allowing others to process their own samples for comparison to samples available on the Portal and allowing us to accept uniformly processed community contributions.

Here, we present the Single-cell Pediatric Cancer Atlas as a resource for all pediatric cancer researchers. The ScPCA Portal provides downloads ready for immediate use, allowing researchers to skip time-consuming data re-processing and wrangling steps. We provide comprehensive documentation about data processing and the contents of files on the portal, including a guide to getting started working with an ScPCA dataset (https://scpca.readthedocs.io/). The ScPCA Portal helps advance pediatric cancer research by accelerating researchers' ability to answer important biological questions.

Results

The Single-cell Pediatric Cancer Atlas Portal

In March of 2022, the Childhood Cancer Data Lab launched the Single-cell Pediatric Cancer Atlas (ScPCA) Portal to make uniformly processed, summarized single-cell and single-nuclei RNA-seq data and de-identified metadata from pediatric tumor samples available for download. Data available on the Portal was obtained using two different mechanisms: raw data was accepted from ALSF-funded investigators and processed using our open-source pipeline, <code>scpca-nf</code>, or investigators processed their raw data using <code>scpca-nf</code> and submitted the output for inclusion on the Portal.

All samples on the Portal include a core set of metadata obtained from investigators, including age, sex, diagnosis, subdiagnosis (if applicable), tissue location, and disease stage. Some investigators submitted additional metadata, such as treatment and tumor stage, which can also be found on the Portal. All submitted metadata was standardized to maintain consistency across projects before adding to the Portal. In addition to providing a human-readable value for the submitted metadata, we also provide an ontology term ID, if applicable. Submitted metadata was mapped to an associated ontology term IDs obtained from HsapDV (age) [10], PATO (sex) [11], NCBI taxonomy (organism) [12], MONDO (disease) [13], UBERON (tissue) [14], and Hancestro (ethnicity, if applicable) [15]. Including ontology term IDs for each sample provides users with standardized metadata terms that can be used across all projects.

The Portal contains data from 500 samples and over 50 tumor types. The total number of samples for each diagnosis is shown in Figure 1A, along with a breakdown of the proportion of samples from each disease stage within a diagnosis group. Figure 1A summarizes all samples from patient tumors or patient-derived xenografts currently available on the Portal. Most samples found on the Portal were obtained from patients with leukemia (n = 192). The Portal also includes samples from brain and central nervous system tumors (n = 154), sarcoma and soft tissue tumors (n = 68), and a variety of other solid tumors (n = 87). Most samples were collected at initial diagnosis (n = 424), with a smaller number of samples collected either at recurrence (n = 64), during progressive disease (n = 10), or postmortem (n = 2). Along with the patient tumors, the Portal contains a small number of human tumor cell line samples (n = 4).

Each of the available samples contains summarized gene expression data from either single-cell or single-nuclei RNA sequencing. However, some samples also include additional data, such as quantified expression data from tagging cells with Antibody-derived tags (ADT), like CITE-seq antibodies [16], or multiplexing samples with hashtag oligonucleotides (HTO)[17] prior to sequencing. Out of the 500 samples, 96 have associated CITE-seq data, and 19 have associated multiplexing data. In some cases, multiple libraries from the same sample were collected for additional sequencing,

either for bulk RNA-seq or spatial transcriptomics. Specifically, 118 samples on the Portal were sequenced using bulk RNA-seq and 94 samples were sequenced using spatial transcriptomics. A summary of the number of samples with each additional modality is shown in Figure 1B, and a detailed summary of the total samples with each sequencing method broken down by project is available in Supplemental Table 1.

Samples on the Portal are organized by project, where each project is a collection of similar samples from an individual lab. Users can filter projects based on diagnosis, included modalities (e.g., CITE-seq, bulk RNA-seq), 10X Genomics version (e.g., 10Xv2, 10Xv3), and whether or not a project includes samples derived from patient-derived xenografts or cell lines. The project card displays an abstract, the total number of samples included, a list of diagnoses for all samples included in the Project, and links to any external information associated with the project, such as publications and links to external data, such as SRA or GEO (Figure 1C). The project card will also indicate the type(s) of sequencing performed, including the 10X Genomics kit version, the suspension type (cell or nucleus), and if additional sequencing is present, like bulk RNA-seq or multiplexing.

Uniform processing of data available on the ScPCA Portal

All data available on the Portal was uniformly processed using scpca-nf, an open-source and efficient Nextflow[18] workflow for quantifying single-cell and single-nuclei RNA-seq data. Using Nextflow as the backbone for the scpca-nf workflow ensures both reproducibility and portability. All dependencies for the workflow are handled automatically, as each process in the workflow is run in a Docker container. Nextflow is compatible with various computing environments, including high-performance computing and cloud-based computing, allowing users to run the workflow in their preferred environment. Setup requires organizing input files and updating a single configuration file for your computing environment after installing Nextflow and either Docker or Singularity. Nextflow will also handle parallelizing sample processing as allowed by your environment, minimizing run time. The combination of being able to execute a Nextflow workflow in any environment and run individual processes in Docker containers makes this workflow easily portable for external use.

When building <code>scpca-nf</code>, we sought a fast and memory-efficient tool for gene expression quantification to minimize processing costs. We expected many users of the Portal to have their own single-cell or single-nuclei data processed with Cell Ranger[19], due to its popularity. Thus, selecting a tool with comparable results to Cell Ranger was also desirable. In comparing <code>alevin-fry</code> [9] to Cell Ranger, we found <code>alevin-fry</code> had a lower run time and memory usage (Supplemental Figure 1A), while retaining comparable mean gene expression for all genes (Supplemental Figure 1B), total UMIs per cell (Supplemental Figure 1C), or total genes detected per cell (Supplemental Figure 1D). (All analyses comparing gene expression quantification tools are available in a public analysis repository[20].) Based on these results, we elected to use <code>salmon alevin and alevin-fry</code> [9] in <code>scpca-nf</code> to quantify gene expression data.

scpca-nf takes FASTQ files as input (Figure 2A). Reads are aligned using the selective alignment option of salmon alevin to an index with transcripts corresponding to spliced cDNA and intronic regions, denoted by alevin-fry as a splici index. The output from alevin-fry includes a gene by cell count matrix for all barcodes identified, even those that may not contain true cells. This unfiltered counts matrix is stored in a SingleCellExperiment object[21] and output from the workflow to a .rds file with the suffix _unfiltered.rds.

scpca-nf performs filtering of empty droplets, removal of low-quality cells, normalization, dimensionality reduction, and cell type annotation (Figure 2A). The unfiltered gene by cell counts matrices are filtered to remove any barcodes that are not likely to contain cells using <code>DropletUtils::emptyDropsCellRanger()</code> [22], with all cells that pass being saved to a

SingleCellExperiment object and .rds file with the suffix _filtered.rds. Then, low-quality cells are identified and removed with miQC [23], which jointly models the proportion of mitochondrial reads and detected genes per cell and calculates a probability that each cell is compromised. The remaining cells are normalized [24] and undergo dimensionality reduction using both principal component analysis (PCA) and UMAP. Finally, cell types are classified using two automated methods, SingleR [25] and CellAssign [26]. The results from this analysis are stored in a processed SingleCellExperiment object saved to a .rds file with the suffix _processed.rds.

To make downloading from the Portal convenient for R and Python users, downloads are available as either SingleCellExperiment or AnnData [27] objects. All SingleCellExperiment objects saved as .rds files are converted to AnnData objects and saved as .hdf5 files in scpca-nf (Figure 2A). Downloads contain the unfiltered, filtered, and processed objects from scpca-nf to allow users to choose to perform their own filtering and normalization or to start their analysis from a processed object.

All downloads from the Portal include a quality control (QC) report with a summary of processing information (e.g., alevin-fry version), library statistics (e.g., the total number of cells), and a collection of diagnostic plots for each library (Figure 2B-G). The knee plot includes all droplets (i.e., before removing empty droplets) sorted based on the total number of UMIs, and those retained after filtering empty droplets are indicated in the plot (Figure 2B). For each cell that remains after filtering empty droplets, the number of total UMIs, genes detected, and mitochondrial reads are calculated and summarized in a scatter plot (Figure 2C). We include plots showing the miQC model and which cells are kept and removed after filtering with miQC (Figure 2D-E). A UMAP plot with cells colored by the total number of genes detected and a faceted UMAP plot where cells are colored by the expression of a top highly variable gene are also available (Figure 2F-G).

Processing samples with additional modalities

scpca-nf includes modules for processing samples with sequencing modalities beyond single-cell or single-nuclei RNA-seq data: corresponding ADT or CITE-seq data [16], multiplexed data via cell hashing [17], spatial transcriptomics, or bulk RNA-seq.

Antibody-derived tags

To process ADT libraries, the ADT FASTQ files were provided as input into scpca-nf and quantified using salmon alevin and alevin-fry (Supplemental Figure 2A). Along with the FASTQ files, scpca-nf takes a tab-separated values (TSV) file with one row for each ADT – containing the name used for the ADT and associated barcode – required to build an ADT-specific index for quantifying ADT expression with alevin-fry. The output from alevin-fry is the unfiltered ADT by cell counts matrix. The ADT by cell counts matrix is read into R alongside the gene by cell counts matrix and saved as an alternative experiment (altExp) within the main SingleCellExperiment object containing the unfiltered RNA counts. This SingleCellExperiment object containing both RNA and ADT counts is output from the workflow to a .rds file with the suffix _unfiltered.rds.

scpca-nf does not filter any cells based on ADT expression or remove cells with low-quality ADT expression. Any cells removed after filtering empty droplets based on the unfiltered RNA counts matrix are also removed from the ADT counts matrix. The workflow calculates QC statistics for ADT counts using DropletUtils::cleanTagCounts() that are stored alongside the ADT by cell counts matrix in the filtered SingleCellExperiment object. The SingleCellExperiment object

containing the filtered RNA and ADT counts matrix and associated ADT QC statistics is saved to an .rds file with the suffix _filtered.rds.

The ADT by cell counts matrix is normalized by first determining the ambient profile and then using that profile to calculate median size factors with <code>scuttle::computeMedianFactors()</code> [28,29]. We skip normalization for cells with low-quality ADT expression, as indicated by <code>DropletUtils::cleanTagCounts()</code>. Although <code>scpca-nf</code> normalizes ADT counts, the workflow does not perform any dimensionality reduction of ADT data; only the RNA counts data is used as input for dimensionality reduction. The normalized ADT data is saved as an <code>altExp</code> within the processed <code>SingleCellExperiment</code> containing the normalized RNA data and is output to <code>a.rds</code> file with the suffix <code>_processed.rds</code>. All <code>.rds</code> files containing <code>SingleCellExperiment</code> objects and associated <code>altExp</code> objects, are converted to <code>AnnData</code> objects and exported as separate RNA(<code>_rna.hdf5</code>) and <code>ADT(_adt.hdf5)</code> AnnData objects.

If a library contains associated ADT data, the QC report output by scpca-nf will include an additional section with a summary of ADT-related statistics, such as how many cells express each ADT, and ADT-specific diagnostic plots (Supplemental Figure 2B-D).

As mentioned above, scpca-nf uses DropletUtils::cleanTagCounts() to calculate QC statistics for each cell using ADT expression but does not filter any cells from the object. We include plots summarizing the removal of low-quality cells based on RNA and ADT counts in the QC report (Supplemental Figure 2B). The first quadrant indicates which cells would be kept if the object was filtered on both RNA and ADT. The other facets highlight which cells would be removed if filtering was done using only RNA counts, only ADT counts, or both. The top 4 ADTs with the most variable expression are also identified and visualized using density plots to show the normalized ADT expression across all cells (Supplemental Figure 2C) and UMAPs – calculated from RNA data – with cells colored by ADT expression (Supplemental Figure 2D).

Multiplexed libraries

To process multiplexed libraries, the HTO FASTQ files are input to scpca-nf and quantified using salmon alevin and alevin-fry (Supplemental Figure 2C). Along with the FASTQ files, scpca-nf requires two TSV files to process multiplexed data: one to build an HTO-specific index for quantifying HTO expression with alevin-fry and a second indicating which HTO was used for which sample when multiplexing the library. The unfiltered HTO by cell counts matrix output from alevin-fry is saved as an alternative experiment (altExp) within the main SingleCellExperiment containing the unfiltered RNA counts. This SingleCellExperiment object containing both RNA and HTO counts is output from the workflow to a .rds file with the suffix _unfiltered.rds.

As with ADT data, scpca-nf does not filter any cells based on HTO expression, and any cells removed after filtering empty droplets based on the unfiltered RNA counts matrix are also removed from the HTO counts matrix and saved to an .rds file with the _filtered.rds suffix. scpca-nf does not perform any additional filtering or processing of the HTO by cell counts matrix, so the same filtered matrix is saved to the processed .rds file with the _processed.rds suffix.

Although scpca-nf quantifies the HTO data and includes an HTO by cell counts matrix in all objects, scpca-nf does not demultiplex the samples into one sample per library. Instead, scpca-nf applies multiple demultiplexing methods, including demultiplexing with DropletUtils::hashedDrops() [30], demultiplexing with Seurat::HTODemux() [17], and genetic demultiplexing when bulk RNA-seq data is available. scpca-nf uses the genetic demultiplexing method described in Weber et al. [31], which uses bulk RNA-seq as a reference for the

expected genotypes found in each single-cell RNA-seq sample. The results from all available demultiplexing methods are saved in the filtered and processed SingleCellExperiment objects.

If a library has associated HTO data, an additional section is included in the QC report output by scpca-nf. This section summarizes HTO-specific library statistics, such as how many cells express each HTO. No additional plots are produced, but a table summarizing the results from all three demultiplexing methods is included.

Bulk and spatial transcriptomics

Multiple libraries were collected for some samples, with the additional libraries being used for bulk RNA-seq and/or spatial transcriptomics. Both of these additional sequencing methods are supported by scpca-nf takes FASTQ from bulk RNA-seq as input, trims reads using fastp [32], and then aligns reads with salmon (Supplemental Figure 3A) [33]. The output is a single TSV file with the gene by sample counts matrix for all samples in a given ScPCA project. This gene by sample matrix is only included with project downloads on the Portal.

To quantify spatial transcriptomics data, scpca-nf takes the RNA FASTQ and slide image as input (Supplemental Figure 3B). As there is not yet support for spatial transcriptomics with alevin-fry, scpca-nf uses Space Ranger to quantify all spatial transcriptomics data [34]. The output includes the spot by gene matrix along with a summary report produced by Space Ranger.

Downloading projects from the ScPCA Portal

On the Portal, users can select to download data from individual samples or all data from an entire ScPCA project. When downloading data for an entire project, users can choose between receiving the individual files for each sample (default) or one file containing the gene expression data and metadata for all samples in the project. Users also have the option to choose their desired format and receive the data as SingleCellExperiment (.rds) or AnnData (.hdf5) objects.

For downloads with samples as individual files, the download folder will include a sub-folder for each sample in the project (Figure 3A). Each sample folder contains all three object types (unfiltered, filtered, and processed) as either SingleCellExperiment (.rds) or AnnData (.hdf5) objects and the QC report for all libraries from the given sample. The objects house the summarized gene expression data and associated metadata for the library indicated in the filename.

All project downloads include a metadata file, single_cell_metadata.tsv, containing relevant metadata for all samples, and a README.md with information about the contents of each download, contact and citation information, and terms of use for data downloaded from the Portal (Figure 3A-B). If the ScPCA project includes samples with bulk RNA-seq, two additional files are included: a gene by sample counts matrix (bulk_quant.tsv) with the quantified gene expression data for all samples in the project and a metadata file (bulk_metadata.tsv).

Merged objects

Providing data for all libraries within a single file makes it easier for users to perform joint gene-level analyses, such as differential expression or gene set enrichment analyses, on multiple samples simultaneously. Therefore, we make a single, merged object available for each project containing all raw and normalized gene expression data and metadata for all single-cell and single-nuclei RNA-seq libraries within a given ScPCA project. The data in the merged object has simply been combined, and no batch-corrected or integrated data is included. If downloading data from a ScPCA project as a

single, merged file, the download will include a single .rds or .hdf5 file, a summary report for the merged object, and a folder with all individual QC and cell type reports for each library found in the merged object (Figure 3B).

To build the merged objects, we created an additional stand-alone workflow for merging the output from scpca-nf, merge.nf (Figure 3C). merge.nf takes as input the processed SingleCellExperiment objects output by scpca-nf for all single-cell and single-nuclei libraries included in a given ScPCA project. The gene expression data stored in all SingleCellExperiment objects are then merged to produce a single merged gene by cell counts matrix containing all cells from all libraries and all shared genes. The genes available in the merged object will be the same as those in each individual object, as all objects on the Portal were quantified using the same index. Any metadata found in the individual processed SingleCellExperiment objects are also merged (e.g., colData, rowData, and metadata). The merged normalized counts matrix is then used to select high-variance genes in a library-aware manner before performing dimensionality reduction with both PCA and UMAP. merge.nf outputs the merged and processed object as a SingleCellExperiment object.

We also account for additional modalities in <code>merge.nf</code>. If at least one library in a project contains ADT data, the raw and normalized ADT data are also merged and saved as an <code>altExp</code> in the merged <code>SingleCellExperiment</code> object. If any libraries in a project are multiplexed, the HTO data is not merged and is not included in the merged object. All merged <code>SingleCellExperiment</code> objects are converted to <code>AnnData</code> objects and exported as <code>.hdf5</code> files. If the merged object contains an <code>altExp</code> with merged ADT data, two <code>AnnData</code> objects are exported to create separate RNA (<code>_rna.hdf5</code>) and ADT (<code>_adt.hdf5</code>) objects.

merge.nf outputs a summary report for each merged object, which includes a set of tables summarizing the types of samples and libraries included in the project, such as types of diagnosis, and a faceted UMAP showing all cells from all libraries. In the UMAP, each panel represents a different library included in the merged object, with all cells from the specified library shown in color, while all other cells are gray. An example of this UMAP showing a subset of libraries from a ScPCA project is available in Figure 3D.

Annotating cell types

Assigning cell type labels to single-cell and single-nuclei RNA-seq data is often an essential step in analysis. Cell type annotation requires knowledge of the expected cell types in a dataset and the associated gene expression patterns for each cell type, which is available in publications or other public databases for some biological contexts. Automated cell type annotation methods leveraging public databases are an excellent initial step in the labeling process, as they can be applied consistently and transparently across all samples in a data set. As such, we include cell type annotations determined using two different automated methods, SingleR [25] and CellAssign [26], in all processed SingleCellExperiment and AnnData objects available for download on the Portal, saving users analysis time.

Annotating cell types with automated methods, like SingleR and CellAssign, require references, either in the form of an annotated bulk or single-cell RNA-seq dataset or matrix of cell types and expected marker genes. Most public annotated reference datasets that can be used with these methods – including those we use for the Portal – are derived from normal tissue, making annotating tumor datasets particularly difficult. Because there are limitations to the annotations provided on the Portal, comparing the two methods and observing consistent cell type annotations across methods can indicate higher confidence in the provided labels. For some ScPCA projects, submitters provided

their own curated cell type annotations, including annotation of tumor cells and disease-specific cell states. These submitter-provided annotations can be found in all SingleCellExperiment and AnnData objects (unfiltered, filtered, and processed).

Two different methods were used for annotating cell types: SingleR and CellAssign. SingleR is a reference-based annotation method that requires an existing bulk or single-cell RNA-seq dataset with annotations. For all libraries on the Portal, we used the BlueprintEncodeData [35,36] dataset from the celldex package [25,doi:10.18129/B9.bioc.celldex?], which includes a variety of normal cell types and provides both the human-readable cell name and cell ontology identifier [37]. In contrast, CellAssign is a marker-gene-based annotation method that requires a binary matrix with all cell types and all associated marker genes as the reference. We utilized the list of marker genes available as part of PanglaoDB [38] to construct organ-specific marker gene matrices with marker genes from all cells for the specified organ. Since many cancers may have infiltrating immune cells, all immune cells were included in each organ-specific reference. For each ScPCA project, we provided the organ-specific marker gene matrix relevant to the disease and tissue type from which the sample was obtained (e.g., for brain tumors, we used a brain-specific marker gene matrix with all brain and immune cell types). The references used with both SingleR and CellAssign only include normal cell types and do not include any tumor cells.

scpca-nf adds cell type annotations from SingleR and CellAssign to all processed SingleCellExperiment objects (Figure 4A). This requires two additional reference files as input to the workflow: a classification model built from a reference dataset for SingleR and a marker gene by cell type matrix for CellAssign . SingleR::trainSingleR() was used to build a classification model from the provided BlueprintEncodeData dataset and create the required SingleR input for scpca-nf. The classification model and processed SingleCellExperiment were used as input for SingleR::classifySingleR(), resulting in annotations for all cells and an associated score matrix. The score matrix containing a score for all cells and each possible cell type and the assigned cell types are added to the processed SingleCellExperiment object output by scpcanf. Simultaneously, processed SingleCellExperiment objects are converted to AnnData objects for classification with CellAssign. CellAssign uses the converted AnnData object and the marker gene matrix to train a model and predict the most likely cell type from the possible cell types in the marker gene matrix. The prediction matrix containing a probability for each cell and all possible cell types and the assigned cell types are added to the processed SingleCellExperiment object output by scpca-nf. The processed SingleCellExperiment object is then converted to an AnnData object to ensure cell type annotations are included in both data formats provided by scpca-nf.

An additional cell type report with information about reference sources, comparisons among cell type annotation methods, and diagnostic plots is also output by scpca-nf. Tables summarizing the number of cells assigned to each cell type for each method are shown alongside UMAPs coloring cells by the assigned cell type. The concordance of cell type annotations assigned between both methods can indicate higher confidence in the provided annotations, so the Jaccard similarity index is used to compare annotations between the two methods. This index is calculated between pairs of labels from each method and ranges from 0-1, with a value close to 1 indicating high agreement and a high proportion of overlapping cells and values close to 0 indicating a low proportion of non-overlapping cells. The Jaccard similarity index is displayed in a heatmap, an example of which is shown in Figure 4B.

The report also includes a diagnostic plot evaluating the confidence of cell type annotations determined by each method. The output from SingleR includes a score matrix containing a score for each cell and all possible cell types found in the reference, where higher scores are associated with assigned cell types. To evaluate confidence in SingleR cell type annotations, the delta median

statistic is calculated by subtracting the median score from the top score for each cell [39]. The distribution of delta median values for each cell type is shown in the cell type report, where a higher delta median statistic for a cell indicates higher confidence in the final cell type annotation (Supplemental Figure 4A). CellAssign calculates the probability that each cell belongs to each possible cell type provided in the reference, and the cell type label with the highest probability is assigned as the cell type for that cell. These values range from 0 to 1, with larger values indicating greater confidence in a given cell type label, so we expect more confident labels to have most values close to 1. An example of the plot included in the report displaying the distribution of all probabilities for each cell type is shown in Supplemental Figure 4B.

If the submitter provided cell types, the submitter annotations are compared to the annotations from both SingleR and CellAssign. A summary of this comparison is included in the cell type report along with a table summarizing the submitter cell type annotations and a UMAP plot where each cell is colored by the submitter annotation. The Jaccard similarity index is calculated for all pairs of cell type labels in submitter annotations and SingleR annotations and in submitter annotations and CellAssign annotations. The results from both comparisons are displayed in a stacked heatmap available in the report, an example of which is shown in Supplemental Figure 5.

Materials and Methods

Data generation and processing

Raw data and metadata were generated and compiled by each lab and institution contributing to the Portal. Single-cell or single-nuclei libraries were generated using one of the commercially available kits from 10x Genomics. For bulk RNA-seq, RNA was collected and sequenced using either paired-end or single-end sequencing. For spatial transcriptomics, cDNA libraries were generated using the Visium kit from 10x Genomics. All libraries were processed using our open-source pipeline, scpca-nf, to produce summarized gene expression data.

Processing single-cell and single-nuclei RNA-seq data with alevin-fry

To quantify RNA-seq gene expression for each cell or nucleus in a library, scpca-nf uses salmon alevin [40] and alevin-fry [9] to generate a gene by cell counts matrix. Prior to mapping, we generated an index using transcripts from both spliced cDNA and unspliced cDNA sequences, denoted as the splici index [9]. The index was generated from the human genome, GRCh38, Ensembl version 104. salmon alevin was run using selective alignment to the splici index with the --rad option to generate a reduced alignment data (RAD) file required for input to alevin-fry.

The RAD file was used as input to the recommended alevin-fry workflow, with the following customizations. At the generate-permit-list step, we used the unfiltered-pl option to provide a list of expected barcodes specific to the 10x kit used to generate each library. The quant step was run using the cr-like-em resolution strategy for feature quantification and UMI deduplication.

Post alevin-fry processing of single-cell and single-nuclei RNA-seq data

The output from running alevin-fry includes a gene by cell counts matrix, with reads from both spliced and unspliced reads for all potential cell barcodes. This output is read into R to create a SingleCellExperiment using the fishpond::load_fry() function. The resulting

SingleCellExperiment contains a counts assay with a gene by cell counts matrix where all spliced and unspliced reads for a given gene are totaled together. We also include a spliced assay that contains a gene by cell counts matrix with only spliced reads. These matrices include all potential cells, including empty droplets, and are provided in the "unfiltered" objects included in downloads from the Portal.

Each droplet was tested for deviation from the ambient RNA profile using DropletUtils::emptyDropsCellRanger() and those with an FDR ≤ 0.01 were retained as likely cells. If a library did not have a sufficient number of droplets and DropletUtils::emptyDropsCellRanger() failed, cells with fewer than 100 UMIs were removed. Gene expression data for any cells that remain after filtering are provided in the "filtered" objects.

In addition to removing empty droplets, <code>scpca-nf</code> also removes cells from downstream analysis that are likely to be compromised by damage or low-quality sequencing. <code>miQC</code> was used to calculate the probability of each cell being compromised [23]. Any cells with a likelihood of being compromised greater than 0.75 and fewer than 200 genes detected were removed before further processing. The gene expression counts from the remaining cells were log-normalized using the deconvolution method from Lun, Bach, and Marioni [24]. <code>scran::modelGeneVar()</code> was used to model gene variance from the log-normalized counts and <code>scran::getTopHVGs</code> was used to select the top 2000 high-variance genes. These were used as input to calculate the top 50 principal components using <code>scater::runPCA()</code>. Finally, UMAP embeddings were calculated from the principal components with <code>scater::runUMAP()</code>. The raw and log-normalized counts, list of 2000 high-variance genes, principal components, and UMAP embeddings are all stored in the "processed" object.

Quantifying gene expression for libraries with CITE-seq or cell hashing

All libraries with antibody-derived tags (ADTs) or hashtag oligonucleotides (HTOs) were mapped to a reference index using salmon alevin and quantified using alevin-fry. The reference indices were constructed using the salmon index command with the --feature option. References were custom-built for each ScPCA project and constructed using the submitter-provided list of ADTs or HTOs and their barcode sequences.

The ADT by cell or HTO by cell counts matrix produced by alevin-fry were read into R as a SingleCellExperiment object and saved as an alternative experiment (altExp) in the same SingleCellExperiment object with the unfiltered gene expression counts data. The altExp within the unfiltered object contains all identified ADTs or HTOs and all barcodes identified in the RNA-seq gene expression data. Any barcodes that only appeared in either ADT or HTO data were discarded, and cell barcodes that were only found in the gene expression data (i.e., did not appear in the ADT or HTO data) were assigned zero counts for all ADTs and HTOs. Any cells removed after filtering empty droplets were also removed from the ADT and HTO counts matrices and before creating the filtered SingleCellExperiment object.

Processing ADT expression data from CITE-seq

The ADT count matrix stored in the unfiltered object was used to calculate an ambient profile with <code>DropletUtils::ambientProfileEmpty()</code>. This ambient profile was used to calculate quality-control statistics with <code>DropletUtils::cleanTagCounts()</code> for all cells remaining after removing empty droplets. Any negative or isotype controls were taken into account when calculating QC statistics. Cells with a high level of ambient contamination or negative/isotype controls were flagged as having low-quality ADT expression, but we did not remove any cells based on ADT quality from the

object. The filtered and processed objects contain the results from running DropletUtils::cleanTagCounts().

ADT data was then normalized by calculating median size factors using the ambient profile with scuttle::computeMedianFactors(). If median-based normalization failed for any reason, ADT counts were log-transformed after adding a pseudocount of 1. Normalized counts are only available for any cells that would be retained after ADT filtering, and any cells that would be filtered out based on DropletUtils::cleanTagCounts() are assigned NA. The normalized ADT data is available in the altExp of the processed object.

Processing HTO data from multiplexed libraries

Although we did not perform any demultiplexing of samples within a multiplexed library, we did apply three different demultiplexing methods. Results from all three methods are included in the filtered and processed SingleCellExperiment objects along with the HTO counts data.

Genetic demultiplexing

If all samples in a multiplexed library were also sequenced using bulk RNA-seq, we performed genetic demultiplexing using genotype data from both bulk RNA-seq and single-cell or single-nuclei RNA-seq [31]. If bulk RNA-seq was not available, no genetic demultiplexing was performed.

Bulk RNA-seq reads for each sample were mapped to a reference genome using STAR [doi10.1093/bioinformatics/bts635?] and multiplexed single-cell or single-nuclei RNA-seq reads were mapped to the same reference genome using STARsolo [41]. The mapped bulk reads were used to call variants and assign genotypes with bcftools mpileup [42]. cellsnp-lite was then used to genotype single-cell data at the identified sites found in the bulk RNA-seq data [43]. Finally, vireo was used to identify the sample of origin [43].

HTO demultiplexing

For all multiplexed libraries, we performed demultiplexing using <code>DropletUtils::hashedDrops()</code> and <code>Seurat::HTODemux()</code>. For both methods, we used the default parameters and only performed demultiplexing on the filtered cells present in the filtered object. The results from both these methods are available in the filtered and processed objects.

Quantification of spatial transcriptomics data

Use of space ranger

Quantification of bulk RNA-seq data

Use of salmon

Cell type annotation

- Implementation of SingleR and CellAssign
- Description of metrics used (e.g., what is the delta median and where does the probability come from)

Generating merged data

• combining counts data and metadata

Converting SingleCellExperiment objects to AnnData objects

• use of zellkonverter

Code and data availability

Figure Titles and Legends

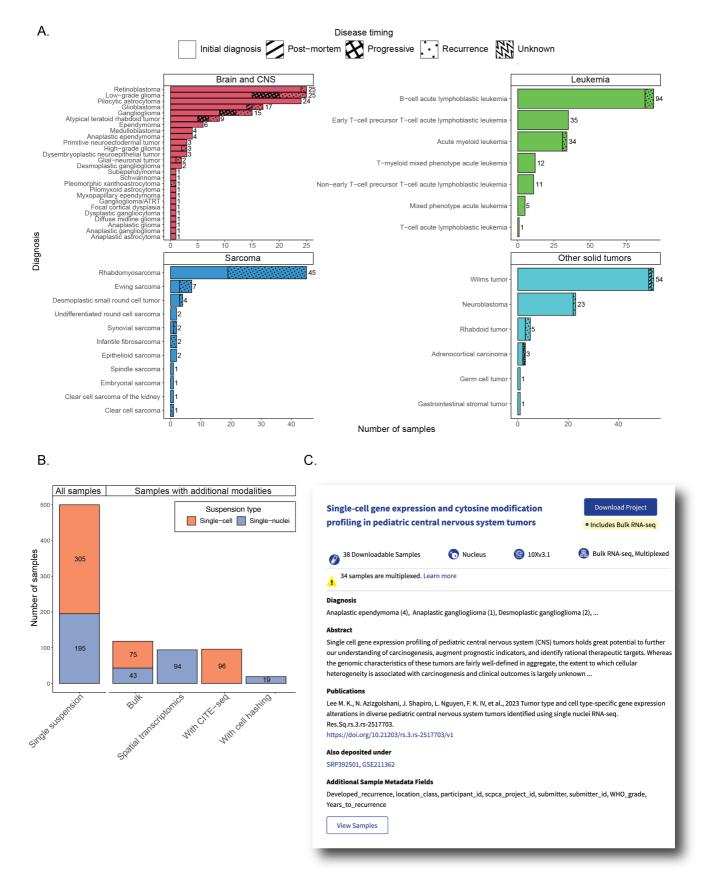

Figure 1: Overview of ScPCA Portal contents.

A. Barplots showing sample counts across four main cancer groupings in the ScPCA Portal, with each bar displaying the number of samples for each cancer type. Each bar is shaded based on the number of samples with each disease timing, and total sample counts for each cancer type are shown to the right of each bar.

B. Barplot showing sample counts across types of modalities present in the ScPCA Portal. All samples in the portal are shown under the "All Samples" heading. Samples under the "Samples with additional modalities" heading represent a subset of the total samples with the given additional modality. Colors shown for each additional modality indicate the suspension type that the single-cell or single-nuclei sample is associated with. For example, 75 single-cell samples and 43 single-nuclei samples have accompanying Bulk RNA-seq data.

C. Example of a project card as displayed on the "Browse" page of the ScPCA Portal. This project card is associated with project SCPCP000009. Project cards include information about the number of samples, technologies and modalities, additional sample metadata information, submitter-provided diagnoses, as well as submitter-provided abstract. Where available, submitter-provided citation information as well as other databases where this data has been deposited are also provided.

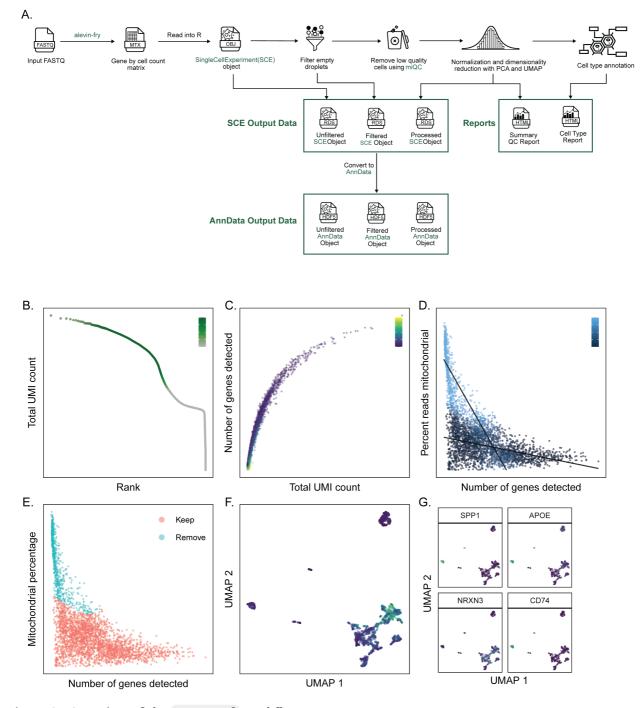

Figure 2: Overview of the scpca-nf workflow.

A. An overview of scpca-nf, the primary workflow for processing single-cell and single-nuclei data for the ScPCA Portal. Mapping is first performed with alevin-fry to generate a gene-by-cell count matrix, which is read into R and converted into a SingleCellExperiment (SCE) object. This SCE object is exported as the Unfiltered SCE Object before further post-processing. Next, empty droplets are filtered out, and the resulting SCE is exported as the Filtered SCE Object. The filtered object undergoes additional post-processing, including removing low-quality cells, normalizing counts, and performing dimension reduction including principal components analysis and UMAP calculation. The object undergoes cell type annotation and is exported as the Processed SCE Object. A summary QC report and a supplemental cell type report are prepared and exported. Finally, all SCE files are converted to AnnData format and exported. Panels B-G show example figures that appear in the summary QC report, shown here for SCPCL000001, as follows.

- B. The total UMI count for each cell in the Filtered SCE Object, ordered by rank. Points are colored by the percentage of cells that pass the empty droplets filter.
- C. The number of genes detected in each cell passing the empty droplets filter against the total UMI count. Points are colored by the percentage of mitochondrial reads in the cell.
- D. miQC model diagnostic plot showing the percent of mitochondrial reads in each cell against the number of genes detected in the Filtered SCE Object. Points are colored by the probability that the cell is compromised as determined by miQC.
- E. The percent of mitochondrial reads in each cell against the number of genes detected in each cell. Points are colored by whether the cell was kept or removed, as determined by both miQC and a minimum unique gene count cutoff, prior to normalization and dimensionality reduction.
- F. UMAP embeddings of log-normalized RNA expression values where each cell is colored by the number of genes detected.
- G. UMAP embeddings of log-normalized RNA expression values for the top four most variable genes, colored by the given gene's expression. In the actual summary QC report, the top 12 most highly variable genes are shown.

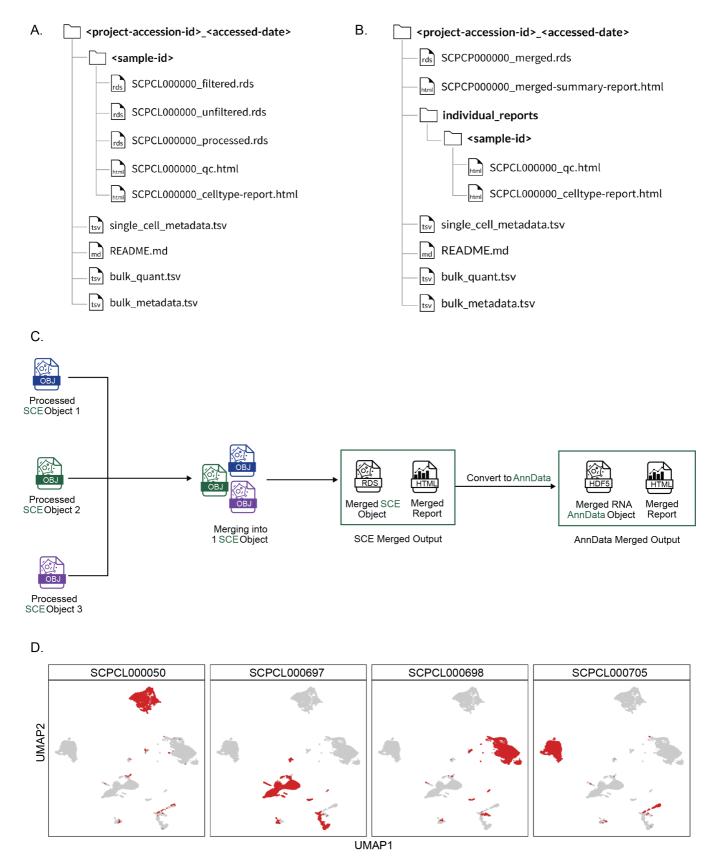

Figure 3: ScPCA Portal project download file structure and merged object workflow.

A. File download structure for an ScPCA Portal project download in SingleCellExperiment (SCE) format. The download folder is named according to both the project ID and the date it was downloaded. Download folders contain one folder for each sample ID, each containing the three versions (unfiltered, filtered, and processed) of the expression data as well as the summary QC report and cell type report all named according to the ScPCA library ID. The single_cell_metadata.tsv file contains sample metadata for all samples included in the download. The README.md file provides information about the contents of each download file, additional contact and citation information,

and terms of use for data downloaded from the ScPCA Portal. The files <code>bulk_quant.tsv</code> and <code>bulk_metadata.tsv</code> are only present for projects that also have bulk RNA-Seq data and contain, respectively, a gene by sample matrix of raw gene expression as quantified by <code>salmon</code>, and associated metadata for all samples with bulk RNA-Seq data.

- B. File download structure for an ScPCA Portal merged project download in SCE format. The download folder is named according to both the project ID and the date it was downloaded. Download folders contain a single merged object containing all samples in the given project as well as a summary report briefly detailing the contents of the merged object. All summary QC and cell type reports for each individual library are also provided in the individual_reports folder arranged by their sample ID. As in panel (A), additional files single_cell_metadata.tsv, bulk_quant.tsv, bulk_metadata.tsv, and README.md are also included.
- C. Overview of the merged workflow. Processed SCE objects associated with a given project are merged into a single object, including ADT counts from CITE-seq data if present, and a merged summary report is generated. Merged objects are available for download either in SCE or AnnData format.
- D. Example of UMAPs as shown in the merged summary report. A grid of UMAPs is shown for each library in the merged object, with cells in the library of interest shown in red and all other cells belonging to other libraries shown in gray. The UMAP is constructed from the merged object such that all libraries contribute an equal weight, but no batch correction was performed. The libraries pictured are a subset of libraries in the ScPCA project SCPCP000003.

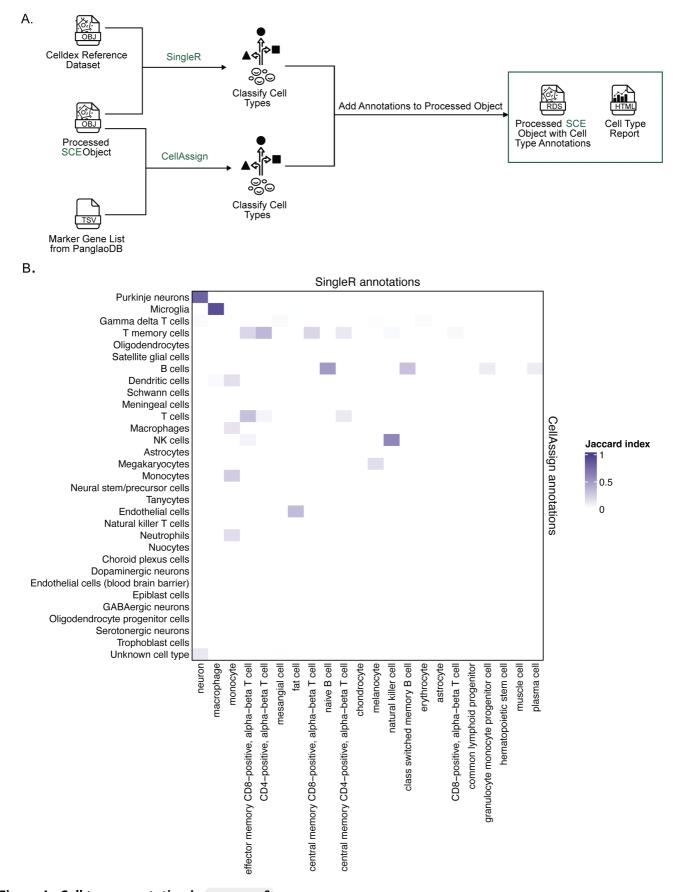

Figure 4: Cell type annotation in scpca-nf.

A. Expanded view of the process for adding cell type annotations within scpca-nf, as introduced in Figure 2A. Cell type annotation is performed on the Processed SCE Object. A celldex [25] reference dataset with ontology labels is used as input for annotation with SingleR [25], and a list of marker genes compiled from PanglaoDB [38] is used as input for annotation with CellAssign [26]. Results from cell type annotation are then added to the Processed SCE Object, and a cell

type summary report with information about reference sources, comparisons among cell type annotation methods, and diagnostic plots is created. Although not shown in this panel, cell type annotations are also included in the Processed AnnData Object created from the Processed SCE Object (Figure 2A).

B. Example heatmap as shown in the cell type summary report comparing annotations with SingleR and CellAssign. Heatmap cells are colored by the Jaccard similarity index. A value of 1 means that there is complete overlap between which cells are annotated with the two labels being compared, and a value of 0 means that there is no overlap between which cells are annotated with the two labels being compared. The heatmap shown is from library SCPCL000498.

Supplementary Figures and Tables

Table S1. Overview of ScPCA Portal Datasets. This table provides descriptions and sample and library counts for each project in the ScPCA Portal.

scpca_project_id: ScPCA project unique identifier. Diagnosis group: Diagnosis group as shown in Figure 1. Diagnoses: Full set of diagnoses for all samples associated with the project. Total number of samples (S): Number of samples associated with the project. Total number of libraries (L): Number of libraries associated with the project. Due to additional sequencing modalities and/or multiplexing, projects may have more libraries than samples. All remaining columns give the number of libraries (as designated with (L)) with the given suspension type or additional modality.

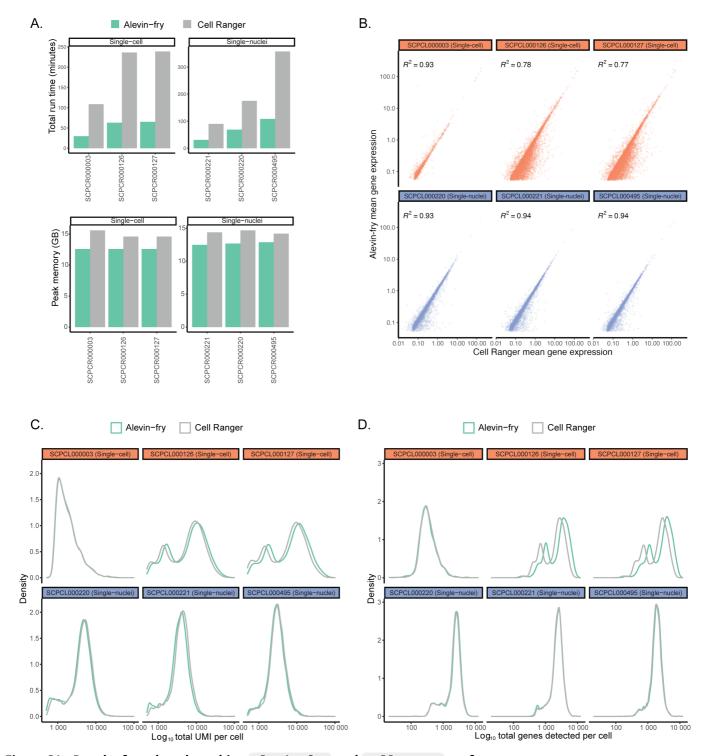

Figure S1: Results from benchmarking alevin-fry and CellRanger performance.

Each panel compares metrics for six representative ScPCA libraries, including three single-cell and three single-nuclei suspensions, obtained from processing libraries with both alevin-fry and CellRanger.

A. Runtime in minutes (top row) and peak memory in GB (bottom row) for six ScPCA libraries processed with alevin-fry and CellRanger. Processing with alevin-fry was consistently faster and more memory-efficient compared to processing with CellRanger.

Panels B-D show only cells present in both the alevin-fry and CellRanger output.

B. Comparison of mean gene expression values for six ScPCA libraries processed with alevin-fry and CellRanger, shown on a log-scale. Each point is a gene, and only genes detected in at least 5

cells are shown. \mathbb{R}^2 values shown in the top left corner of each panel reflect broad agreement in mean gene expression values between platforms.

- C. Comparison of log total UMI counts for six ScPCA libraries processed with alevin-fry and CellRanger. Distributions reflect broad agreement in the total UMI count per cell between platforms, although alevin-fry returned slightly higher values for certain single-cell libraries.
- D. Comparison of log total genes per cell for six ScPCA libraries processed with alevin-fry and CellRanger. Distributions reflect broad agreement between platforms in the total number of genes per cell between platforms, although alevin-fry returned slightly higher values for certain single-cell libraries.
